

Fewer Topics? A Million Topics? Both?!

On Topics Subsets in Test Collections

Abstract When evaluating IR run effectiveness using a test collection, a key question is: what search topics should be used? We explore what happens to measurement accuracy when the number of topics in a test collection is reduced, using the Million Query 2007, TeraByte 2006, and Robust 2004 TREC collections, which all feature more than 50 topics, something that has not been examined in past work. Our analysis finds that a subset of topics can be found that is as accurate as the full topic set at ranking runs. Further, we show that the size of the subset, relative to the full topic set, can be substantially smaller than was shown in past work. We also study the topic subsets in the context of the power of statistical significance tests. We find that there is a trade off with using such sets in that some significant results will be missed, although the loss of statistical significance is smaller than when selecting random subsets. We also find topic subsets that can result in a test collection with very low accuracy, even when the subset has a large cardinality. These sets are examined and their properties described. Finally, we examine whether clustering of topics is a good strategy to find good topic subsets. Our

1 Introduction and Background

When evaluating the effectiveness of Information Retrieval (IR) systems, the design of the measurement process has been examined by researchers from many ‘angles’: e.g. the consistency of relevance judgments; the means of minimizing judgments while maintaining measurement accuracy; and the best formula for measuring effectiveness. One aspect – the number and type of queries (*topics* in TREC terminology) needed in order to measure reliably – has been discussed less often. In general, there has been a trend in test collection construction of increasing the number of topics, but without much consideration of the benefits of such an approach. In many areas of measurement via sampling, it is generally accepted that there are diminishing returns from increasing the sample size. Beyond a certain point, improvements in measurement accuracy are small and the cost of creating the sample becomes prohibitive. We are not aware of work in IR that establishes if such an optimal sample size exists.

Some work has been conducted on whether smaller topic sets (*subsets*) could be used in a test collection, examining early TREC ad hoc collections (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013), and the 2009 Million Query (MQ) Track (Carterette et al, 2009a,b). These approaches, in general, ask how similarly a set of retrieval runs are ranked when using such a subset versus a full set of topics. Note that in these experiments, the full set of topics is taken to be the *ground truth*. The similarity of the two rankings is measured using Kendall’s Tau (henceforth, τ). Figure 1 shows an example result from this work, taken from Guiver et al (2009). On the x-axis are topic subsets of increasing cardinality, the y-axis measures τ . Three types of subset are shown for each cardinality:

- Best – the subset of a given cardinality that results in a ranking that is closest to the ranking of runs using the full topic set;
- Average – the average τ of all the topic subsets examined;
- Worst – the topic subset that results in a ranking that is furthest from the ranking of runs from the full topic set.¹

The best correlation curve shows that even when using a topic subset of cardinality 6, a relatively high τ (> 0.8) can be found. The curve for the average topic set reaches a τ of 0.8 at cardinality 22. The generality of this basic result was questioned by Robertson (2011), and revisited again by Berto et al (2013) with results that confirmed the original conclusions. Carterette et al

¹ Guiver et al (2009) use the terminology Best/Average/Worst, and we adopt it in this paper in order to be consistent with past work.

Fig. 1 Kendall’s τ correlation curves for AH99, adapted from Guiver et al (2009, Figure 2).

(2009a) conducted similar experiments though only measuring the average. However, they also examined different topic types, which will be discussed later.

There are a number of limitations with these past studies:

1. The researchers examined relatively small ground truth topics sets: $n = 50$ (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013) and $n = 87$ (Carterette et al, 2009a). There is no knowledge of the generality of the results when n is much larger. Because the existing studies sampled from topic sets that are relatively small, as the cardinality of the subset becomes a substantial fraction of the ground truth set, the properties of the sample and the full set are guaranteed to become similar and the correlations between the rankings of runs will tend to 1. The observation in Figure 1 that a topic subset of cardinality 22 has similar properties to the full set of 50 topics may not hold with a larger ground truth. This limitation is particularly serious in the light of recent work by Sakai (2016b), who showed that for test collections to have reasonable statistical power, ground truth topic sets size should be at least around 200, if not higher. Therefore the results obtained on the basis of a ground truth of far fewer than 100 topics call for further confirmation on higher cardinalities.
2. A limitation of past work (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013) is that the statistical significance of the differences between runs was not taken into account: τ values do not explain if a different run ranking is due to minor fluctuations or to statistically significant differences in measurement values. Again, this is a notable omission, in the light of recent work from Sakai (2014) that emphasizes the link between topic set size and statistical power.
3. Almost no characterization of the best topic sets has been attempted (apart some results on stability of such sets, see e.g. Figures 5 and 6 in Guiver et al (2009)). However, it seems intuitive that smaller topic sets should be obtained by removing redundancy, for example by clustering topics and selecting representatives from each cluster.

In this paper we address three research questions:

- RQ1. What effect does a larger ground truth topic set have on the correlation curves? Does using a larger ground truth increase confidence in the results obtained from past work? Does the minimum cardinality of a topic subset, needed in order to achieve a high correlation, depend on the cardinality of the ground truth?
- RQ2. Do the results on topic subset size hold when statistical significance is considered?
- RQ3. Is clustering an effective strategy to find the best topic sets? Does the choice of a specific clustering setting (features, algorithms, distance functions, etc.) make important differences? If so, what clustering settings are most effective in finding topic sets featuring high correlations?

In the rest of the paper, Section 2 frames the context of this research by analyzing related work. Section 3 describes the experimental setting. Section 4 discusses the results related to first research question RQ1. Section 5 focuses on RQ2 and addresses the statistical significance issues. Section 6 examines RQ3, about clustering. Section 7 summarizes the contribution of this paper and sketches future developments.

2 Related Work

In addition to the previously mentioned work examining topics (Guiver et al (2009); Robertson (2011); Berto et al (2013)), a wide variety of studies analyze the components of test collections. Here, we focus on those that consider the number of topics needed and topic subsetting.

2.1 Number of Topics

Buckley and Voorhees (2000) looked at the accuracy of common evaluation measures relative to the number of topics used. They suggested using at least 25 topics, though having more was better. The authors concluded that 50 topics produce reliable evaluations. The conclusion on the number of topics was broadly confirmed by Carterette et al (2006) who considered a larger number of topics (200). They also showed that the minimum number needed to separate the effectiveness of two runs depends on how similar those runs were.

While the methods used in earlier work to determine the appropriate number of topics for a test collection involved a range of empirical approaches, Webber et al (2008) proposed the use of statistical power analysis when comparing the effectiveness of runs. The authors argued that a set of nearly 150 topics was necessary to distinguish runs. Building on suggestions by Sanderson and Zobel (2005), they also argued that using more topics with a shallow assessment pool was more reliable than using few topics with a deep assessment pool.

Using Test Theory ideas described by [Bodoff and Li \(2007\)](#), [Urbano et al \(2013\)](#) examined test collection reliability considering all aspects of the collection. The authors tabulated their measures of reliability across a large number of TREC collections, and suggested that the number of topics used in most current test collections is insufficient.

More recently, [Sakai \(2014, 2016b\)](#) used power analysis to argue that more topics than are currently found in most test collections are required. He showed that many significant results may be missed due to the relatively small number of topics in current test collections. He concludes that potentially, hundreds of topics are required to achieve reasonable power in current test collections.

2.2 Topic Subsets

Subsequent to the work of [Mizzaro and Robertson \(2007\)](#) on topic subsets, [Hauff et al \(2009\)](#) presented three approaches to measure effectiveness estimation using topic subsets: greedy, median Average Precision (AP), and estimation accuracy. [Hauff et al \(2010\)](#) then presented evidence showing that the accuracy of ranking the best runs depended on the degree of human intervention in any manual runs submitted, and went on to show that this problem can be somewhat alleviated by using a subset of “best” topics. [Cattelan and Mizzaro \(2009\)](#) also studied whether it is possible to evaluate different runs with different topics. [Roitero et al \(2017\)](#) generalized the approach to other collection and metrics, further investigating the correlations between topic ease and its capability of predicting system effectiveness.

In contrast to the work conducted by [Mizzaro and Robertson](#) – which looked for best and worst subsets in a “bottom up” approach, finding any topics that would fit into each subset – [Carterette et al \(2009a\)](#) took a “top down” approach. They manually split the topics of the MQ collections into subsets based on groups of categories from [Rose and Levinson \(2004\)](#). They found little difference examining the groups. They also looked at different combinations of hard, medium, and easy topics (determined by the average score that runs obtained on the topics) and found similar conclusions to earlier topic subset work.

In related work, [Hosseini et al \(2011b\)](#) presented an approach to expand relevance judgments when new runs are evaluated. The cost of gathering additional judgments was offset by selecting a subset of topics that discriminated the runs best, determined using Least Angle Regression (LARS) and convex optimization, up to a maximum topic set cardinality of 70. Later, [Hosseini et al \(2011a\)](#) used convex optimization to select topics which needed further relevance judgments when evaluating new runs. The algorithm estimates the number of unjudged documents for a topic and identifies a set of query-document pairs that should be judged given a fixed budget.

[Kutlu et al \(2018\)](#) developed a method for topic selection based on learning-to-rank; they took into account the effect of pool depth and focused on deep vs. shallow judging.

Table 1 Test collections used for all experiments.

Acronym	TREC Collection	Year	Topics	Total Runs	Used Runs
AH99	Ad Hoc	1999	50	129	96
R04	Robust	2004	249	110	82
TB06	TeraByte	2006	149	61	49
MQ07	Million Query	2007	1153	29	26

3 Experimental Setting and Data

We describe the test collections, methods, and means of evaluation used in our experiments.

3.1 Data and Collections

Our experiments require test collections with more than 50 topics, and for which a sufficient number of runs are available to be analyzed. The three instantiations of the Million Query track collections feature more than 1,000 topics each year that are sampled from a query log. We use the data from the 2007 track. However, the Million Query datasets are not free from disadvantages: runs are evaluated using the statMAP metric, which is slightly different from classical Mean AP (MAP),² and not as many runs are available (25-35). In addition, working with so many topics presents computational challenges. Therefore, we also use two other test collections: the TREC 2004 Robust track and the TREC 2006 TeraByte track, using automatic runs only. To enable a comparison with the results obtained in previous studies (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013), we also use the TREC 8 ad hoc (AH) track (1999). Table 1 summarizes the four test collections. As is usual for the analysis of TREC run data (see e.g. Voorhees and Buckley (2002)), we remove the least effective runs, obtaining the number of runs in the last column. For AH99 we removed the 25% least effective runs to have the same situation as in prior work (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013); for R04 we did the same; for TB06 and especially MQ07, which feature a smaller number of runs, we removed fewer (only 20% and 10%, respectively) by manually examining the distribution of run effectiveness values, and pruning runs with a clear drop in effectiveness compared to others that are ranked higher.

3.2 Software

For our analysis, we employed the BestSub software that was used in previous studies (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013). Because the number of all possible topic subsets of cardinality c of a set of full cardinality n

² The effect of statMAP is discussed in more detail in Section 3.3

grows exponentially as $\binom{n}{c} = \frac{n!}{c!(n-c)!}$, the software uses a heuristic to cope with the combinatorial explosion. The heuristic builds the best set of cardinality $c + 1$ on the basis of the best set of cardinality c by looking at those subsets of cardinality $c + 1$ that differ from the best set of cardinality c by at most k topics. In the previous studies, $k = 3$. Using such a heuristic search means that the best and worst curves are not optimal and that there could be topic sets that are even better or worse. Although these sets might be different, correlation values should not change significantly, as shown by Guiver et al (2009, Section 5.1).

Since in our case $n \gg 50$ (we have 149, 249, and 1,153 as n values), the complexity is even higher. This would mean that using BestSub would be impractical, with months if not years of computation time required to obtain the correlation values for the MQ07 curves, even by resorting to lower k values. We therefore re-implemented BestSub to incorporate an evolutionary algorithm. This change has no effect when tested on small cardinalities: both versions of BestSub produce almost completely overlapping and graphically indistinguishable correlation curves. For higher cardinalities, the curves obtained from the result of the new evolutionary algorithm are not distant from interpolating the curves from BestSub. We also needed stable results to work on the percentiles (as we discuss below). For this reason, the average correlation curves are obtained by averaging one million samples in place of 50,000 that was used in past work. Again, this larger sample did not substantially affect the average curves.

3.3 Effectiveness Metrics

The MQ07 collection differs from the others in that it uses statAP and statMAP, rather than AP and MAP, as its primary evaluation measure. statMAP (Allan et al, 2007; Carterette et al, 2009a; Pavlu and Aslam, 2007) can be described as a version of MAP that creates the pool with a sampling strategy: in place of pooling the first n documents retrieved in at least one run, as done in classical TREC (and used to calculate MAP), when using statMAP each document is associated with an *inclusion probability*, used both to decide whether a document is in the pool, and to weight the importance of the document when computing the metric. Since the differences between statMAP and MAP may have implications for our analysis, we consider two approaches for comparing them. The first is to produce scatter plots showing how the run ranks change when using the two metrics. This has been explored several times, and on different datasets, in previous work, e.g. over AH99 data by Pavlu and Aslam (2007, Figure 7), and over TB06 data by Allan et al (2007, Figure 5); both analyses showed that while variations exist, these are limited.

A second approach is to compare the correlation curves produced by BestSub when using statMAP and MAP. To do so, we re-evaluated AH99 using statMAP. Since several versions of statMAP exist, to be sure to reproduce the one used in MQ07, with the right parameters, we took particular care

Fig. 2 Kendall’s τ correlation curves for AH99, on a subset of runs, for both MAP and statMAP.

in the process: statMAP works on a deeper pool, so we selected only the 57 runs in AH99 for which the statMAP sampling algorithm does not select any unjudged documents, and used the same software used for MQ07,³ thereby implementing “stratified sampling” (Pavlu and Aslam, 2007, Section 2.4), where each document has a probability of being sampled that is proportional to its rank in the run outputs. We then compared statMAP and MAP in two ways: through scatter plots, which confirmed the above mentioned results from prior work; and by running BestSub using both statMAP and MAP. The (best, average, and worst) correlation curves that we obtained for statMAP and for MAP are shown in Figure 2. The lines are very similar, and often overlap or cross each other. In fact the differences are much larger when comparing them with the full AH99 dataset, such as in Figure 1; this is likely due to the different (smaller) number of runs, and the range of metric values, which have a larger impact than using statMAP in place of MAP. We therefore conclude overall that, although statMAP does create some differences, these appear to be smaller than the differences introduced by other variables, and that using statMAP in place of MAP should not introduce any strong bias into our analysis. This confirms the results obtained by previous studies (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013), where the evaluation metric usually did not make any noticeable difference.

4 RQ1: Larger Ground Truth

We first present an overview of the results, followed by descriptions of best, average, and worst curves and analyses of RQ1.

³ <http://trec.nist.gov/data/million.query07.html>

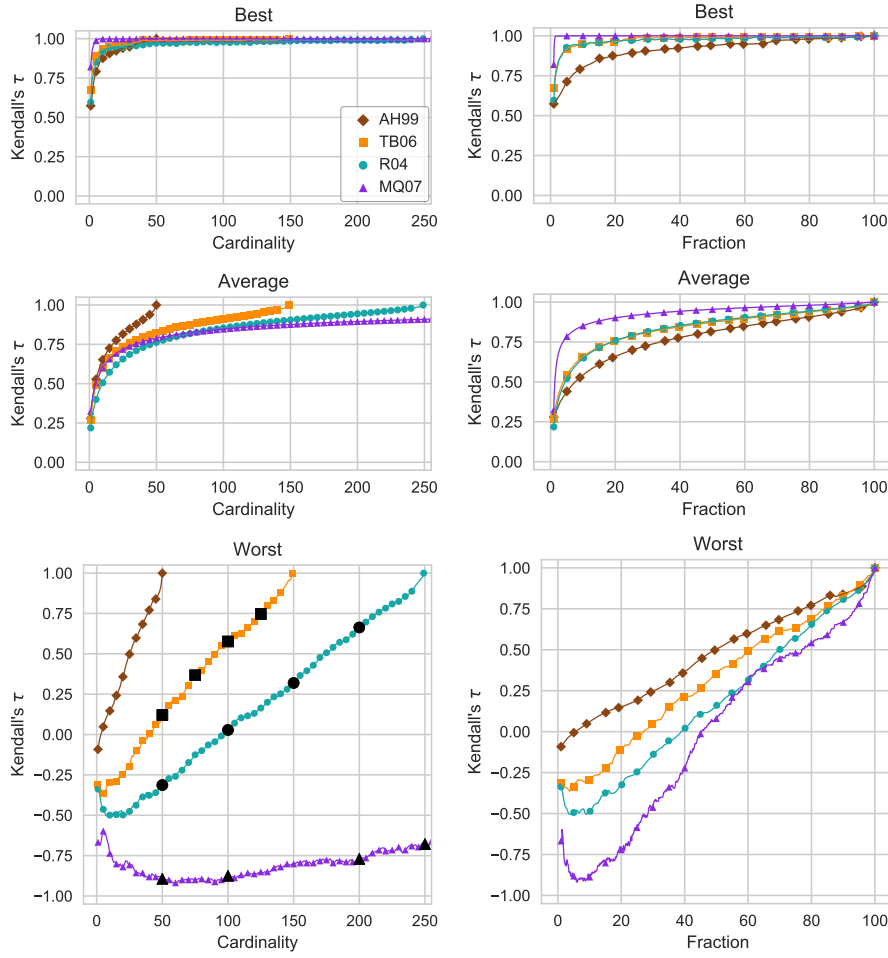

Fig. 3 Kendall's τ correlation curves for absolute cardinalities (left-side, cardinalities up to 250) and fraction of full set (right-side). Black markers in the Worst curves are further analyzed in Figure 5.

4.1 General Results

Figures 3 and 4 show correlation charts for the three new datasets TB06, R04, MQ07, as well as AH99 (correlation values are obtained using statMAP for MQ07 and MAP for the other datasets). Correlation is measured using τ . Unlike Figure 1, we plot best, average, and worst in separate charts. We also plot the best and worst 1% topic subsets found. In the graphs on the left side of the figures, the x-axis shows subset size (cardinality); in the graphs on the right, the x-axis measures the subset size as a fraction of the cardinality of the ground truth set. For graphical reasons, the charts on the left have 250 as maximum cardinality: by doing so, we can fully represent the curves for AH99,

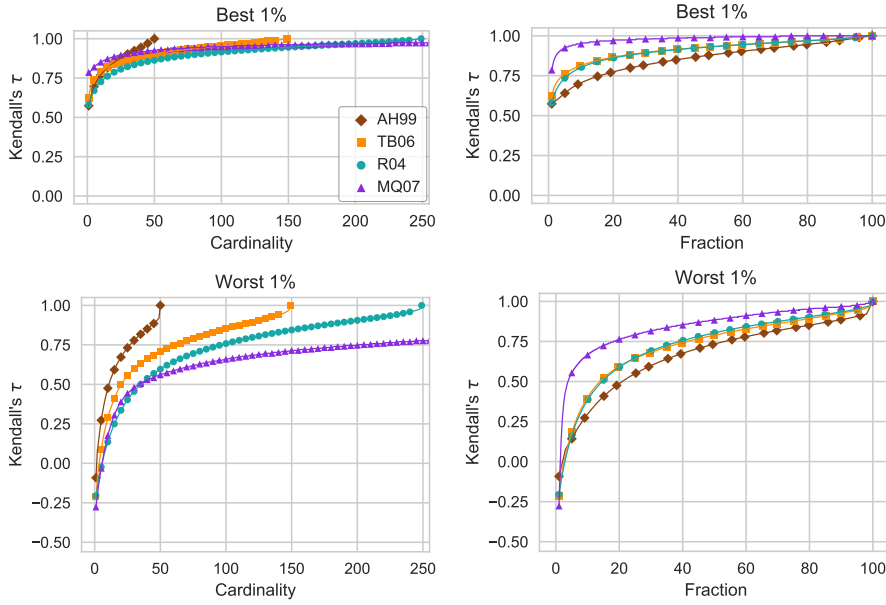

Fig. 4 Kendall's τ correlation curves for absolute cardinalities (left-side, cardinalities up to 250) and fraction of full set (right-side).

TB06, and R04, avoiding to squeeze them, allowing the curves to be clearly seen at low cardinalities. As a consequence, the MQ07 curves are truncated, but their complete trend can be seen in the charts on the right. Again for graphical reasons – to avoid making the charts too cluttered – we do not plot the markers for all cardinalities. Rather, in the left hand side charts only the markers at cardinalities that are multiples of 5 are shown, plus cardinality 1 and full set cardinality. Similarly, in the right hand side charts, a marker is plotted at each fraction multiple of 5% (or, when not available because of rounding, the closest value), plus the 1% marker. Note that the lines in the charts are not mere interpolations between those emphasised markers: they follow the real values at each cardinality.

While there are similarities between the current charts and those previously published, the best and average curves seem higher when the ground truth cardinality increases. The worst curves are lower, particularly for the MQ07 dataset. For example, for the MQ07.W⁴ curve, a τ of 0 is reached at around 0.45 of the full cardinality set (around 500 topics) and a τ of 0.5 is reached at 0.8 (around 900 topics). In other words, it would appear that one can build a subset of around 500 MQ topics that ranks the runs randomly, compared to the ground truth. A subset of 900 topics can be found that ranks the runs in

⁴ We use the suffix B/A/W to indicate the correlation curve for the best/average/worst topic set.

a still different way to the ground truth set. We analyze these curves in more detail in the following.

4.2 Best, Average, and Worst Curves

4.2.1 Best Correlation Curves

From the best correlation curves we see that fewer topics can potentially be used on ground truth cardinalities of $n \gg 50$: the MQ07_B curve is highest, followed by R04_B and TB06_B, which are in turn both consistently higher than AH99_B. This answers the research question RQ1 by supporting the hypothesis that having a larger topic set as ground truth increases the possibility of finding a subset of good topics, thereby leading to higher correlation curves.

A further confirmation of that hypothesis comes from the fraction curves (right-side). Here, the two best curves R04_B and TB06_B are almost exactly overlapping, and they both stay well above the best curve AH99_B. The MQ07_B is even higher. Compared with the previous three studies (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013) we see that when using a higher cardinality ground truth (149, 249, or 1, 153 topics in place of only 50), run effectiveness can be predicted by using even fewer topics.

When comparing across the four test collections, it is prudent to examine other properties of the collections that might impact on the trend observed. One can see from Table 1 that as well as a change in ground truth topic cardinality, there is also a change in the number of runs associated with each of the test collections and that this might impact on the τ values. However, as illustrated by Sanderson and Soboroff (2007), it is the range of scores that a set of runs have that impacts on τ and other correlation measures, while the number of runs is not a factor leading to higher curves. As will be seen in Figure 5, the range of scores of the runs is similar across the four test collections.

4.2.2 Average Correlation Curves

When examining the average τ across topic subsets, we see that τ for AH99_A is higher than R04_A, TB06_A, and MQ07_A: on average, by selecting a random subset of topics of a given cardinality, this appears to be a better predictor of run rankings in the AH99 dataset than in R04, TB06, and MQ07. Returning to the example in Figure 1 an average topic subset of cardinality 22 drawn from the collections with larger ground truth has a lower τ than on AH99.

The corresponding fraction curves tell a different story however: on average, by selecting a given fraction of the ground truth, the topic subset of AH99 turns out to be a worse predictor of run rankings than that of R04, TB06, and MQ07. Collections with larger ground truths appear to need a smaller fraction of topics to achieve high values of τ .

A particular feature of the MQ07_A curve is that its trend seems more similar to the best than to the average curves of the other datasets. For this dataset, on average, a good prediction of run ranks can be obtained with a small fraction of topics (around 5-10%) and a very good prediction of run ranks can be obtained with 20%. This result needs to be examined on other test collections with similarly large topic sets.

The curves for R04 and TB06 on the fraction charts are almost exactly overlapping. This might be an indication that a ground truth of cardinality 50 is somewhat different from a larger ground truth. There might be some numerical/statistical effect that does not appear when using only 50 topics.

4.2.3 Worst Correlation Curves

The most striking difference between AH99 and the larger datasets is in the worst curves: whereas best and average are broadly similar to past work, the worst curves are quite different.

The correlation values for the worst curves are strongly negative. This is a novel situation, not observed in the previous three studies (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013) where τ values were at worst negative with a low absolute value (around -0.2). Negative correlations show topic subsets that evaluate runs in broadly opposite ways. Also, the negative correlation values in R04.W persist for cardinalities much larger than 50, the usual number of topics used in evaluation exercises. The MQ07_W curve is even lower and stays below -0.5 up to 250 (and, as can be seen from the fraction curve on the right, even up to 300).

It is striking that on MQ07, a subset of more than 250 topics can be found that negatively correlates with the ground truth topic set. As mentioned above, a set of around 45% of the MQ07 topics (around 500 topics) results in a τ of zero.

Note, the reason three of the curves drop as the cardinality of the topic sets increase from 1 is due to the degrees of freedom there are when searching for topic subsets that are the worst: the value of $\binom{n}{c}$ initially increases as c gets larger. Therefore, the range of possible topic sets that are searched to find the worst also gets larger.

4.3 Best and Worst First Percentile Curves

Given the extreme nature of the best and worst curves, we also computed the average τ of the best and worst 1st percentile of topic subsets. Figure 4 shows the resulting charts.

The Best 1% curves emphasize that although the quest of finding the best topic subsets is rather difficult since they are extremely rare, reasonably good results that can more easily be obtained in practical cases do exist. The Worst 1% curves are less worrying than the Worst ones, since they do not feature the same extremely low, if not negative correlations. Although these curves

look more like those from the Average, it is worth noting that when trying to find subsets of topics for an effective test collection, a low positive correlation is not satisfying either. For example, the R04 1st percentile curve has low τ (< 0.6) even for cardinality 45, and the MQ07 1st percentile curve has a τ of about 0.75 at cardinality 250. These are not extremely unlikely topic sets, and it is possible that some test collections have been created with topics that rank runs quite differently from what might be expected.

4.4 Worst Subset Analysis

Although exceptionally rare, the very worst topic subsets feature extremely low correlations. In this section we try to better understand how the subsets produce such low τ correlations.

4.4.1 Overlap

Examining intersections between the best and worst topic subsets, we find that there is a quite large overlap between them: at cardinality 100, R04 and MQ07 have a topic overlap of around 40%. This means that it is possible to select a set of 40 topics, then to add to it either a first or a second set of 60 (different) topics, and obtain completely different, even almost opposite, rankings of runs.⁵

A possible explanation for this overlap could be that there are two small subsets of topics, one good and one bad, that are used to build the low cardinality best and worst sets; then a set of common “neutral” topics are added to both to obtain the higher cardinality sets. However, this needs further study, as this possibility is not consistent with the data, since the 40% overlap can be found from cardinality 50 up to 200.

4.4.2 Comparing Worst with Best

It is also possible that some conceptual features of the topic subsets exist that could explain the low correlations. Therefore, some of the worst topic subsets are characterized here for analysis. We manually selected illustrative topic subsets that have low τ correlations and high cardinalities:

- TB06: cardinalities 50, 75, 100, and 125.
- R04: cardinalities 50, 100, 150, and 200.
- MQ07: cardinalities 50, 100, 200, and 250.

These are the subsets represented by black markers in Figure 3. Figure 5 shows scatter plots for these subsets. We see that the effectiveness measure computed on the worst subset (y-axis) usually has both a smaller range and lower values

⁵ Note, the overlap that we find might be an effect of the heuristic used; we can say no more than it is possible to build a best and a worst set of topics with a high overlap.

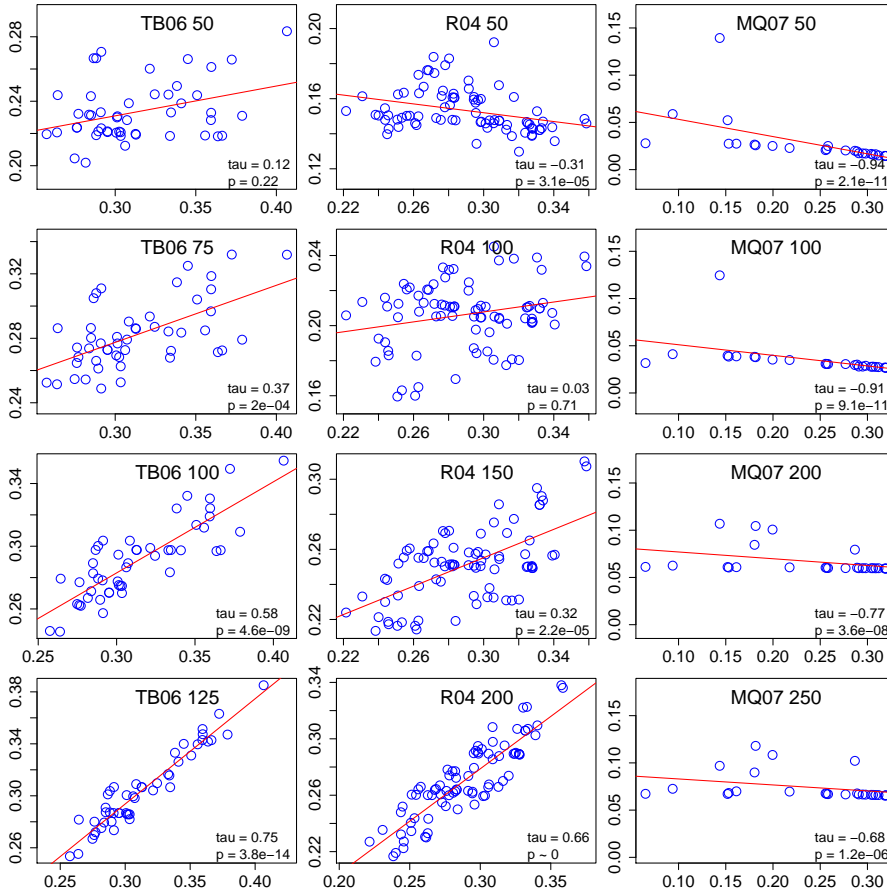

Fig. 5 Scatter plots for some selected notable worst topic subsets. Each dot is a run, the x-axis shows MAP (statMAP for MQ07) computed on the ground truth full topic set, the y-axis shows effectiveness computed on the worst subset indicated. The τ of the correlation along with the significance of the correlation (indicated by a p value) is detailed on each plot.

when compared to the measure computed on the ground truth set (x-axis). This is especially true for MQ07, but the same effect can also be found on the other datasets. To better understand this observation, the mean effectiveness over all topic subset cardinalities was computed for the best and worst topic subsets. The results are shown in the left part of Table 2. It can be seen that the best subsets contain topics that lead to higher effectiveness values than the worst subsets. The right part of the table shows the Δ between the average subset effectiveness and the ground truth effectiveness. As might be expected, in all cases the best subsets contain topics that lead to values more similar to ground truth effectiveness.

Table 2 Effectiveness measures (MAP, except statMAP for MQ07) over the best and worst subsets and between ground truth.

	Av. Effectiveness of Subset				Subset Δ from Ground Truth			
	AH99	TB06	R04	MQ07	AH99	TB06	R04	MQ07
Best	0.298	0.277	0.264	0.148	0.017	0.036	0.025	0.092
Worst	0.201	0.263	0.224	0.049	0.080	0.050	0.066	0.191

5 RQ2: Statistical Significance

We now turn to RQ2. While the previous results demonstrate that it is possible to find topic subsets that lead to run rankings that are highly correlated with the rankings obtained when using a full (ground truth) set of topics, in order for one run to be considered more effective than another, a statistical significance test is usually carried out. The number of topics that are used to evaluate effectiveness has a direct impact on significance calculations. For example, for a paired t-test, the denominator of the test statistic includes the sample size (Sheskin, 2007), and the larger the sample, the lower the p -value. In IR experiments the sample is the number of topics. Some analysis of statistical significance is therefore due in the fewer topics scenario. We present two approaches to do so in the next two subsections.

5.1 Power Analysis

Sakai (2016b) recently proposed three methods to compute the cardinality of a topic set size to ensure that a test collection has enough statistical power to distinguish effectiveness of the systems/runs. The methods compute the estimated topic set size on the basis of three different tests:

- Method 1, based on t-test, and used when one wants to compare two system scores, or the score of one system against all the other systems.
- Method 2, based on one way ANOVA, and used when one wants to compare the scores of more than two systems, or to compare all systems against each other.
- Method 3, similar to Method 1, but it allows one to specify a confidence interval δ to ensure that the outcome of this test is bounded with precision δ . As Sakai points out: “a wide confidence interval that includes zero implies that we are very unsure as to whether systems X and Y actually differ”.

We computed and/or estimated the parameters required by Sakai’s methods and ran them on our four collections, using the software (Excel spreadsheets) provided by Sakai. Tables 3, 4, and 5 show the results.

The topic set size cardinalities in Table 3 are those required to find statistical significance when comparing two systems, or a system against a set of other systems (e.g. when trying to understand if system s_1 is better than

Table 3 Number of estimated topics using the first method, based on t-test. The required σ_t^2 parameter has values 0.096 (for AH99), 0.071 (TB06), 0.100 (R04), and 0.118 (MQ07). The values in bold represent the maximum and minimum estimated number of topics for the given parameters, for each collection.

both systems s_2 and s_3). The three parameters are: α , which is the probability of Type I error (to find a difference that does not exist; that is, one concludes that s_1 is more/less effective than s_2 but this is not true); β , which is the probability of Type II error (not to find a difference that does exist; that is, one does not conclude that s_1 is more effective than s_2 when it is in fact better); and $minD_t$, which is the minimum detectable difference in MAP values. We use the same values for these three parameters as adopted by Sakai in the examples in his paper. $minD_t$ is computed considering the estimated within-system variance from past collections, σ^2 . To compute σ^2 we used, as

Sakai suggests, Formula (36) of Sakai (2016b), that is the residual variance from one-way ANOVA: we applied Formula (36) to our collections when using the AP (statMAP for MQ07) metric.

The values in the table (the estimated required number of topics) range from 16 to 706. Besides the considerations that could be made on the values of the three parameters α , β , and $minD_t$ (probabilities of Type I and II errors, and the minimum detectable difference), what is important to note for our purposes is that quite often the required number of topics is even higher than the cardinality of the full topic set size for the corresponding collection.

This is even more true when using the second method (based on ANOVA), see Table 4: in this case values range from 54 to 3446. The parameters for this method have a similar meaning to the previous method based on the t-test, with some technical differences. It is important to notice that the estimates obtained with the second method are probably more related to the approach in this paper, since we generally compare all the systems together, rather than a single system to the other ones. The third method returns intermediate results (see Table 5).

This analysis led to reappraising the results on the best correlation curves: whereas it is true that small good topic sets exist, using them would, unsurprisingly, lead to less statistical power (which is defined according to Sakai as $1 - \beta$, and represents the capability of finding a difference between system scores which is statistically significant), or in other words it is a move away from the number of topics required to have such statistical power.

We note that this approach (Sakai, 2016b) does not directly quantify how much statistical power we are losing when using the smaller good topic sets. In future work we intend to further explore the relationship between the factors of (sub-)topic set size and quality, and statistical power. Moreover, this method does not consider what kind of errors are made: when using fewer topics, there are different possible specific outcomes besides the result of a statistical test: one might find significance for a sub-set while according to the full set of topics there is not, or vice versa one might not find significance for a sub-set while for the full there is; one might even find statistically significant disagreement; and so on. For these reasons, we conducted another, more general, experiment, described in the following subsection.

5.2 Statistically Significant Agreement and Disagreement

We conduct an empirical investigation into the relationship between the number of topics considered in an IR experiment and the observed outcomes of statistically significant differences between runs. We first discuss some methodological issues and then describe our experimental results.

5.2.1 Methodology

Consider a typical IR effectiveness experiment, where a researcher is seeking to demonstrate that one retrieval approach is superior to another. The researcher chooses a test collection consisting of (say) 50 topics, and generates two sets of 50 effectiveness scores (two runs). If the mean score for one run is higher than that for the other, it is standard to carry out a significance test such as a paired t -test. This will indicate whether the two scores are indeed likely to come from populations with different means, at some specified level of confidence.

We are interested in investigating the question: if the researcher had carried out the same experiment but with a subset of topics, would the same results have been observed? More concretely, consider a test collection with a ground truth set, G , of topics of cardinality b . Let there also be a subset of topics, S , with cardinality a , where $a < b$. For a pair of runs X and Y , calculate their MAP using topic set S , and carry out a paired 2-tailed t -test to determine whether the difference is statistically significant. Repeat the process for the same pair of runs, but using the topic set of full cardinality, G . There are five possible outcomes (Moffat et al, 2012):

- SSA: run X is significantly better than run Y on both topic sets, S and G .
- SSD: run X is significantly better than run Y on one topic set, but Y is significantly better than X on the other topic set.
- SN: one run is significantly better than the other on topic set S , but there is no significant difference on topic set G .
- NS: one run is significantly better than the other on topic set G , but there is no significant difference on topic set S .
- NN: there is no significant difference between the runs on either topic set.

The first two letters of each label indicate the outcome of the experiment (Significant or Not significant) on topic set S and G , respectively, while A and D stand for Agreement and Disagreement, respectively. Note that only two of the five outcomes, SSA and NN, are cases where consistent conclusions would be drawn from the experiments regardless of which topic set is used. For the other three, a researcher who happened to use a topic subset S would reach a different conclusion about relative run effectiveness, than if they had used the ground truth G .

When considering topic subsets, it is desirable to maximize the number of SSA and NN cases (SSA if the researcher is looking for a publishable result), and to avoid SN and NS cases (where significant differences are found with one topic set but not with the other) and in particular SSD (where significant differences are found with both topic sets, but with different runs being indicated as being better).

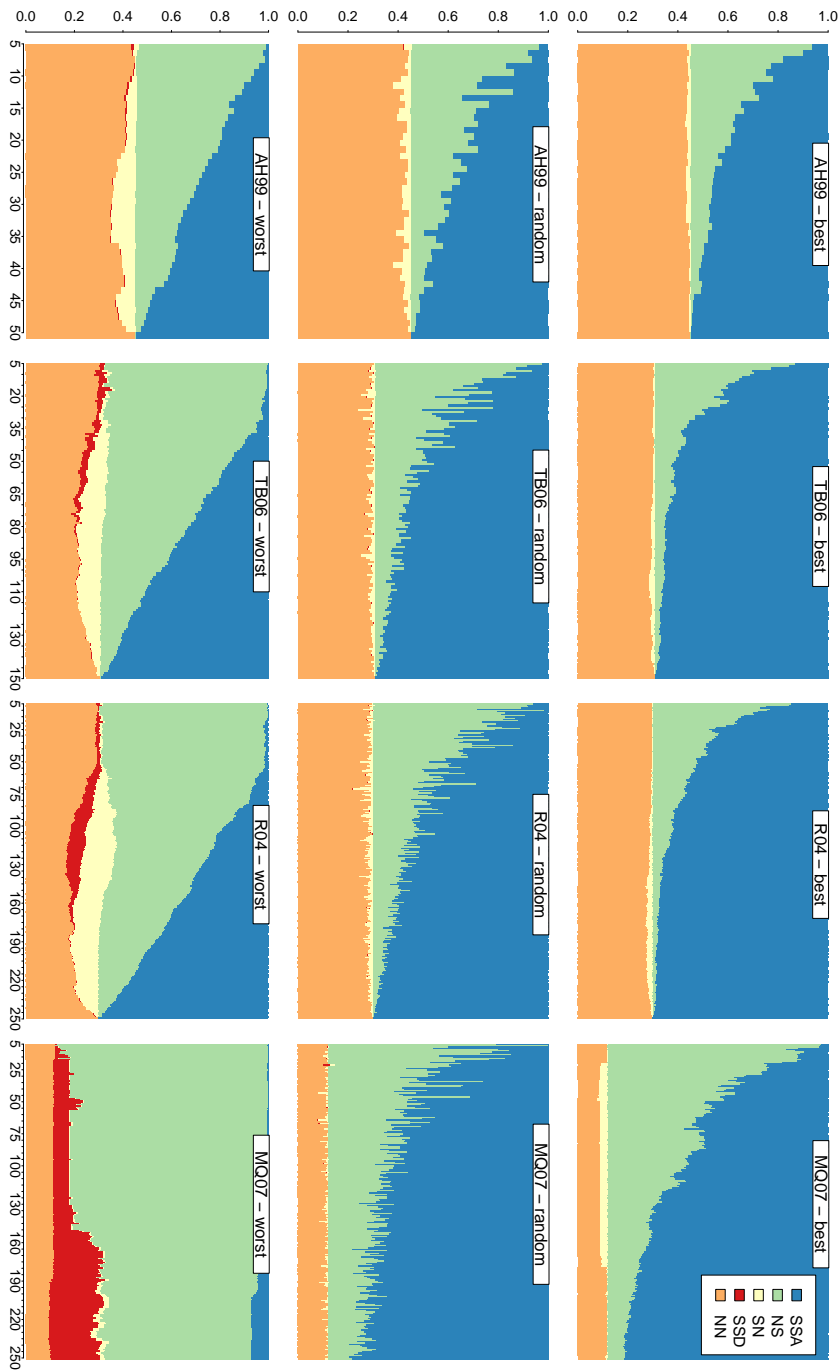

Fig. 6 The results of typical IR effectiveness experiments, showing the proportion of cases where statistically significant differences (two-tailed paired t-test, $p < 0.05$) are observed between two runs when comparing them using a reduced cardinality (shown on the x-axis) compared to the full topic set for a collection.

5.2.2 Results

The results of the simulated experiments are shown in Figure 6 for the four collections (columns), and for the best, random,⁶ and worst subsets (rows). For each sub-figure, the x-axis shows the cardinality of topic set S , which is being compared to the full cardinality ground truth, topic set G . The y-axis shows the proportion of occurrences for each of the five experimental outcomes: SSA (blue), NS (green), SN (yellow), SSD (red) and NN (orange). It can be observed that when the subsets reach their maximum cardinality (on the right of the plots), only two outcomes are possible, SSA and NN. This must be the case, since at full (ground truth) cardinality S and G are the same, and so the outcomes of the two experiments are identical. (Recall that in the MQ07 collection, subsets do not reach full cardinality by 250.) When the full topic sets are used, SSA is dominant, accounting for around 55–70% of cases. This is reassuring, since it shows that using the full collections, it is possible to statistically distinguish between the runs more often than not.

The figures also clearly confirm that the larger the cardinality, the higher the likelihood that the same significant evaluation results will be observed as when using the ground truth topic set. The NS class shows the cases where a significant difference would be found between two runs using G , but no corresponding difference is found when using S . For these cases, the reduction in topic set cardinality has compromised the ability of the significance test to identify significant effects, a false negative. Moreover, when comparing the charts “horizontally”, the NN orange areas decrease with the full cardinality of the dataset, in both best and random, while the SSA blue areas increase. As expected, results tend to be statistically significant more often when the full cardinality of the ground truth is higher.

Considering the best, random, and worst topic subsets, over all four collections, as cardinality increases, the best subsets lead to the most rapid maximizing of the SSA class (and quickest reduction of the NS class), though on the MQ07 collection, the best subset is only somewhat better than random. The best subsets, besides allowing to use fewer topics in evaluation, also lead to finding SSA results (both in agreement with the ground truth and statistically significant) more often than random topic subsets.

The worst subsets lead to experimental significance results that have the least correspondence with the ground truth topic set. Perhaps unsurprisingly, the heuristic that selected the best and worst subsets, which was optimized to maximize and minimize τ respectively, also maximized and minimized on significance.

The size of the SN category (false positive) is generally very small – there are few cases where significant differences are detected on S while no significance is found on G .

⁶ Here, for speed of calculation reasons only a single random topic subset is drawn from the set of all topic subsets of a given cardinality. The histograms of random are consequently more “spiky” than if we averaged several random subsets. However, the broad signal of the result is still visible in the plots.

The most problematic case, SSD, where one run is significantly better than another on topic set S , while the other run is found to be significantly better on topic set G , is fortunately rare, although it should be noted that it is possible, for all collections except AH99, to find a (worst) subset of topics of rather high cardinality that would lead to such contradicting results. In particular, for the MQ07 collection, even by cardinality 250, for the worst subset, the proportion of SSD cases is substantially higher than SSA cases. In other words, the worst chart for MQ07 shows that we can not only generate a topic subset of cardinality 250 with strong, and statistically significant, negative correlation with the full set (as already shown by the MQ07 series in the worst plots in Figure 3 and, more in detail, by the last plot of Figure 5), but moreover that the “aberrant” subset of MQ07 topics of cardinality 250 would also feature a very small amount of SSA and NN, and many NS and even SSD. Experiments using that subset would lead a researcher to derive a statistically significant result that is very different from the full set. Whether this is a temporary manifestation, or is maintained into higher cardinalities, needs to be investigated in future work. However, it must be noted that best, random, and worst charts for MQ07 are consistent with the other datasets (once the fact that we do not reach the full cardinality for MQ07 is taken into account).

By and large the NN cases stay constant over the best and random topic subsets and there is only some variation of these on the worst subset.

5.2.3 Conclusions

Overall, this analysis demonstrates that while it is possible to find a subset of topics that lead to run effectiveness rankings that are highly correlated with rankings from a ground truth set, a side effect of doing so is that a researcher is sacrificing the ability to identify statistically significant differences between runs.

An experimenter using a topic subset in general does not risk having to deal with false positive significant results, however, they do risk having a number of false negatives in their experiments. As seen in the ratio of SSA to NS in the plots, the magnitude of the problem reduces as the subset cardinality increases. Indeed many experimenters might view a small amount of NS acceptable if it means they can build their test collection more quickly using fewer resources.

Perhaps more worryingly, since the topics used in IR test collections are typically not sampled randomly and independently from the population of all topics, one might question the general applicability of statistical tests in IR evaluation, and how much confidence one should attach to such results in terms of estimating the generalizability of experiments to larger topic sets.

5.2.4 Caveat

It should be noted that this simulation of typical IR experiments includes a large number of pairwise significance tests. One might therefore argue that cor-

rections for multiple testing, such as the Bonferroni correction (Feise, 2002), should be applied. However, while individual researchers might use such corrections from time to time, the fact is that IR test collections are used again and again, often to compare against standard baselines, and there is no way of knowing what corrections should be made to account for all (reported as well as unreported) tests that are ever carried out by the population of IR researchers as a whole. Not applying multiple comparison corrections is therefore a more accurate simulation of the typical IR experimental environment. We note that the t -test is the most widely used statistical test in IR experiments (Sakai, 2016a); however, we also repeated the experiment using the Wilcoxon signed rank test instead of the t -test, and the trends were consistent.

6 RQ3: Topic Clustering

We now turn to RQ3. As already stated in Section 1, it seems intuitive that by (i) clustering the topics, and (ii) selecting representatives from each cluster, the topic set obtained should be more representative of the full ground truth than an average or random topic subset of the same cardinality. Therefore, a topic clustering process should be a natural, simple, and effective strategy to find good topic subsets. However, such a process could involve many different settings. We present several approaches, their results, and a discussion on clustering effectiveness.

6.1 Experimental Setting

We start by defining the experimental settings and notation that are common to the experiments described below.

6.1.1 The Clustering Process

As usual, we denote with n the number of topics and with $c \in \{1, \dots, n\}$ the cardinality of the topic subset; also, $m \in \{2, \dots, n\}$ is the number of clusters obtained when performing a clustering process. Our method is composed by the following three steps.

1. For each cardinality c , we build a set of m clusters.
2. Then a topic subset of cardinality c is formed by selecting random representatives from each cluster; in the following we refer to this selection method as *one-for-cluster*.
3. Finally, we build the usual correlation curves, and we compare these one-for-cluster series with the random topic selection, which is the average series (such as the ones represented in Figure 3, left-side, second row).

We use *hierarchical* clustering with a *complete linkage* method, and the *cosine similarity* as the distance function. We also try variants, as specified

below. We also do 10,000 repetitions to compute the one-for-cluster series, to avoid noise.⁷

6.1.2 Feature Space

We take as topic features the AP (or statAP) values over the run population, by clustering topics in a multi-dimensional space, where each dimension is the effectiveness on a specific run, and each topic is a vector of AP (statAP) values. The idea is that topics that have similar AP values for all runs are redundant: one topic should be as effective as all of the “similar” ones. Clustering should group together those topics that have similar scores, and by picking representatives from each cluster we should select a good topic subset. For each dataset, the number of dimensions is therefore the number of runs (the last column in Table 1). We also experiment with a variant of this approach, as detailed below.

6.1.3 Number of Clusters and Topic Cardinality

We can think of two possible overall settings, that affect Steps 1 and 2 above. For each cardinality c and number of clusters m :

- We can perform clustering with the constraint $c = m$; we refer to this setting with the term *cardinality-driven clustering*;
- We can determine the number of clusters a priori, independently from c , and subsequently select the topic subset; we refer to this setting with the term *cardinality-independent clustering*.

Both settings have pros and cons. The first approach forces the clustering algorithm to produce a clustering of exactly $m = c$ clusters, which might be unnatural for certain c values: for example, if the topics are naturally clustered in two clusters, forcing them into three will produce clusters that are less complete and more heterogeneous, thus potentially of lower quality. However, once the clusters are formed, the selection of topics is straightforward, since there is the guarantee that when c topics are to be represented, there are exactly c clusters. Furthermore, even if the $c = m$ constraint might lead to obtain unnatural clusters for certain c values, in general just decent clusters, even if not perfect, might be of a sufficient quality to guarantee higher correlation values for the one-for-cluster series than for random topic selection.

Conversely, with the second setting, the topics can be clustered in a more natural way, but then the selection process is slightly more complicated: there is no equivalence between the number of clusters and the number of topics to select, thus there is not a unique selection method, and the selection process has to take into account the empty clusters that might occur during the process. Finally, whereas with the first setting the choice of the number of

⁷ We tried with up to 1 million repetitions, but the series are already stable with 1,000 repetitions.

clusters m is straightforward and determined, with the second setting m is a parameter to be chosen, and it is not clear which criteria could be used. In the following sections we analyze both settings, starting with the first one.

6.2 Cardinality-driven Clustering

6.2.1 A First Attempt

We compute the clustering as described above, with the constraint $c = m$; then, we compare the one-for-cluster with the average series. It is found, however, that this clustering of topics approach does not result in any topic subset having a τ correlation higher than the average; indeed usually τ is even lower. There are multiple possible explanations for this behavior. First is the choice of clustering algorithm. Therefore, we tried different variations of the clustering, for example, using K-means (with the algorithm variations Hartigan-Wong, Lloyd, and MacQueen⁸), and/or using different distance functions (including as different kinds of proximity measures⁹ both linear metrics, e.g., Euclidean, Manhattan, Divergence, etc., and similarity-angular distances, e.g., Cosine, Correlation, Jaccard, Phi, etc.), or using different methods to join clusters (thus different linkage techniques including single, average, mean, median, Ward). τ was never found to be higher than average for any of these clustering methods, and we can be confident that these negative results are not affected by a particular clustering setting.

A second possible explanation is related to the feature vector: our feature vectors are in a high-dimensional space, and therefore most of the distances tend to be similar, and vectors tend to be orthogonal. To be more precise, as soon as the number of dimensions grows, the number of possible distance values drops. This is a well known phenomenon, referred to as “the curse of dimensionality” (Rajaraman and Ullman, 2011, Chapter 7), and it occurs for both linear and angular distance values (Cosine, Euclidean, and Manhattan). This could of course harm the clustering process. To address this limitation we tried to combine clustering with dimensionality reduction, as described in Section 6.2.2. Finally, in this setting we have the constraint that the number of clusters m must be equal to the topic subset cardinality c , and that could lead to forming unnatural clusters, as already mentioned; we discuss this third possible explanation in Section 6.2.3.

⁸ See the R function “kmeans” in the “stats” package (<https://stat.ethz.ch/R-manual/R-devel/library/stats/html/kmeans.html>), and “k-means” of “scikit-learn” for Python 3 (<http://scikit-learn.org/stable/modules/generated/sklearn.cluster.KMeans.html>).

⁹ For an exhaustive list see the R package “proxy” (<https://cran.r-project.org/web/packages/proxy/proxy.pdf>), and the “Distance computations” section of Python 3 (<https://docs.scipy.org/doc/scipy/reference/spatial.distance.html>).

Fig. 7 Kendall's τ correlation curves for the four datasets: averaged (thinner gray lines), and obtained using clustering (thicker darker lines).

6.2.2 Dimensionality Reduction

To deal with the curse of the dimensionality effect, a second attempt makes use of Principal Components Analysis (PCA). To express around 85-90% of the total variance of the data, three components/dimensions are needed for AH99, R04, and TB06, and five for MQ07. Each topic vector is then heavily reduced, to very few components: from the values in the last column of Table 1 to 3, 3, 3, and 5, respectively. We then repeat the clustering process with the same primary settings as above ($c = m$, hierarchical algorithm, cosine distance, and complete linkage).

With PCA, the results are different to clustering. Figure 7 compares the correlation curves for average subsets, which are gray and thin in the figure, with the correlation curves obtained with the one-for-cluster method: the latter are usually above the former. Moreover, the differences between one-for-cluster and average correlation values are statistically significant for most of the cardinalities: in around 90% of the $50 + 249 + 149 + 250 = 698$ total cases for the four collections, the difference is statistically significant according to the Wilcoxon signed rank test, $p < .01$, and there are no noticeable differences across datasets (the number of statistically significant cases varies between 86% and 92%).

In summary, topic subsets found by clustering combined with dimensionality reduction show correlations with the ground truth that are statistically significantly higher than average / random subsets. However, the difference is rather small: although clustering helps, it helps just a little. Indeed, considering the results of Figure 7, one might be tempted to conclude that clustering of topics is not an effective technique, at least with the constraint $c = m$. Also, the oscillations of the one-for-cluster correlation curves that can be seen in Figure 7 call for an explanation. To address these issues, and to present a detailed analysis of clustering of topics with the constraint $c = m$, we perform another experiment, described in the next section.

6.2.3 A Simulation Experiment

To further understand what is happening during the clustering process, and to further investigate the capabilities of the clustering process with the constraint $c = m$, as well as the limitations, we design the following experiment, in an artificial scenario. The idea of this simulation is to show what happens with clustering of topics in an ideal situation, where the data is distributed with a minimum and controlled amount of noise, and the topics are artificially clustered in a neat way. This represents the most favorable scenario for the topic clustering process. We will discuss the same experiment for cardinality-independent clustering in Section 6.3.

The artificial clustering experiment is as follows. We select s topics, called *seeds*. We experiment with choosing as seeds the topics from a collection in two ways: either randomly, or choosing a set of well separated topics after projecting the multidimensional topic space onto two dimensions. In the following, we report the results of the random selection only, as the other one provides a comparable result.

Given the seed topics, we form a set of new topics, placing in the neighborhood of each seed r fictitious topics in a hyper-sphere of radius ϵ ; we call these topics the *surrounding* topics of the seed topics. Thus, we simulate an ideal scenario for clustering of topics where we have s ideal clusters of r topics each; 2ϵ is the maximum distance, in terms of AP (statAP), between two topics in the same ideal cluster. Note that, the higher ϵ , the higher the probability that the ideal clusters overlap, and therefore that a topic, during an automatic clustering process, is placed in a cluster different from that of its seed, and of the other topics in the same ideal cluster.

We now perform clustering as we did in Section 6.2.2; we use the constraint $c = m$, PCA, hierarchical clustering with a complete linkage method, and the cosine similarity as the distance function. We vary the three parameters as follows: $s \cdot r = 150$, with $s \in \{15, 30, 50\}$, and thus $r \in \{10, 5, 3\}$, and $\epsilon \in \{0.01, 0.02, 0.05\}$.

Results of the experiment are shown in Figure 8. In panel (a), the one-for-cluster series for the three topic seeds (15, 30, and 50) are represented with different colors, and the different line types (continuous, dashed, and dotted) identify the different ϵ values (0.01, 0.02, and 0.05). The figure also shows

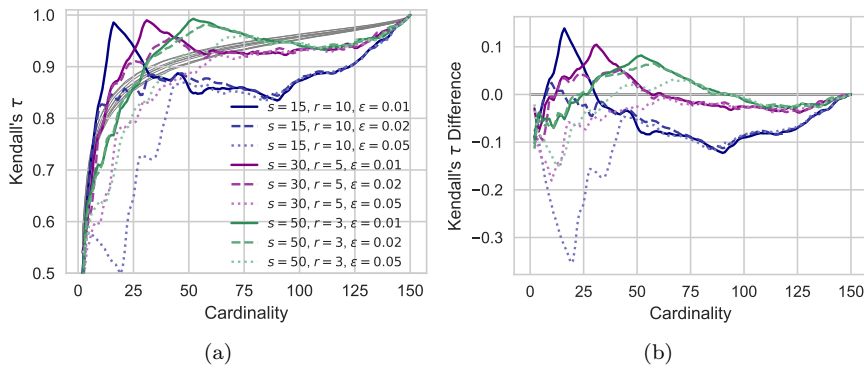

Fig. 8 On the left, Kendall’s τ correlation values for the average and the one-for-cluster series. On the right, the series obtained subtracting the average series to the one-for-cluster one. The three series represent the three number of topic seeds: 15, 30, and 50, represented with different colors. The different colors and line types of the series represents different epsilon values. The series are smoothed using a mobile mean with a window of three elements. The gray lines represent the average series.

the average series as gray thin lines. Figure 8(b) shows the same data with a different representation. Each series is obtained subtracting the corresponding average series from the one-for-cluster one. The horizontal gray line highlights the value of zero: if the series in the plot is above zero it means the one-for-cluster series has higher correlation values with the ground truth than the average one, if the series is below zero vice-versa the average series has higher correlation values.

We can draw several conclusions from these results. Looking at the highest peaks, one can see that they occur at cardinalities corresponding with the number of ideal clusters (equal to the number of seeds s): the clustering approach works well if the topics can be “naturally clustered” in a number of clusters corresponding to the cardinality of the subset of a few good topics; this is true when all the surrounding topics are placed in the same cluster as the corresponding seed topic. However, the further the cardinality is from this ideal number of clusters (the number of seeds), the more the correlation of the one-for-cluster series decreases, and becomes comparable with the random selection of topics (the average series), or even worse.

Focusing on the “negative” peaks (e.g. for the series with 15 seeds, for $\epsilon = 0.05$ at the cardinalities around 20, and for all three ϵ values at cardinalities around 90) we note that the negative peaks achieve lower values of correlation as ϵ increases, as expected. These negative peaks confirm that, if a natural clustering of topics is not possible, clustering of topics worsens the selection of a few good topics with respect to random selection. This effect can be explained by looking at the composition of the clusters produced during the cluster process, where we notice that surrounding topics of different seeds indeed tend to be clustered together even when ϵ is small. This is likely caused by the constraint $c = m$, that forces the number of clusters. Furthermore, the

desired behavior would be that when increasing cardinalities, the clusters split into balanced sub-clusters; for example, with $s = 15$, at cardinality 30 each cluster containing the seed should split into 2 balanced clusters, at cardinality 45 into 3 balanced clusters, and so on. However, in practice this is not the case: on the contrary, there is always a very small number of clusters split into smaller and smaller clusters, while other larger clusters remain intact. This results in a “bad” clustering of topics: in the one-for-cluster series the majority of topics come from the more fragmented clusters. We can say that the more fragmented clusters weight more than the other in the evaluation; on the contrary, the average series chooses topics uniformly.

Finally, it is also interesting to note that there are some lower positive peaks in the series. For example, see in the chart on the right the series with 30 seeds with $\epsilon = 0.02$, for the cardinalities around the values of 18, 22, 39, and 41. These lower peaks suggest that it is not always the case that the data can be explained with only one number of clusters, but multiple number of clusters are possible to obtain a natural clustering of topics.

Summarizing, it seems reasonable to conclude that the $c = m$ constraint makes clustering ineffective for most of the cardinalities, even in the most favorable scenario. Moreover, considering real data, ϵ will be quite high, since in general it is very unlikely that our vectors (topics) have very similar values, with just a very small ϵ difference. Thus cardinality-driven clustering does not seem to be a feasible technique to be applied on real data. For this reason, in the following we study cardinality-independent clustering, starting by repeating the simulation experiment of this section.

6.3 Cardinality-independent Clustering

In our previous experiments, the number of clusters is equal to the number of selected topics. Now, we perform clustering of topics with a number of clusters m independent from the topic subset cardinality c and hopefully matching the number of clusters in a natural clustering.

6.3.1 The Clustering Process

In the case of cardinality-independent clustering, differently from cardinality-driven clustering, m is a parameter to be chosen. There are several ways of selecting such a parameter. The first alternative is to try all possible values from 2 to the number of topics. A second approach could be to rely on some index of goodness of the obtained clusters. Another possibility is to look at the results of cardinality-driven clustering: in cardinality-driven clustering, due to the constraint $c = m$, the positive peaks in the one-for-cluster series (see Figures 7 and 8) correspond to m values leading to an effective clustering of topics; this fact can be exploited to choose the value of m for the cardinality-independent clustering: we can focus on the cardinalities corresponding to the positive peaks of the one-for-cluster series in cardinality-driven clustering. In

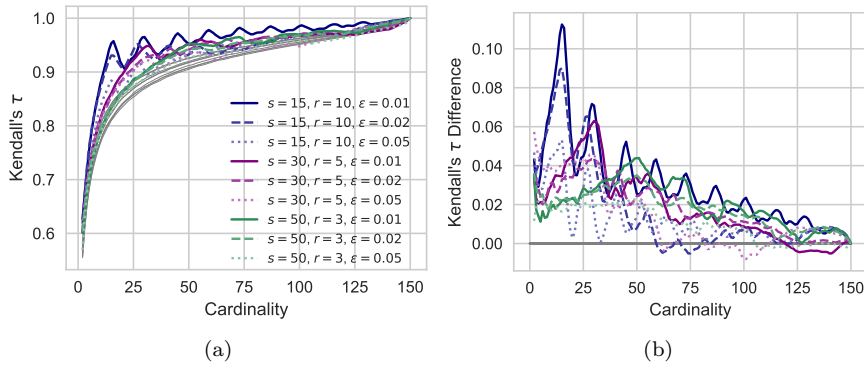

Fig. 9 Results of the cardinality-independent clustering for the artificial experiment. Compare with Figure 8.

the following we investigate the latter approach; we also tried various indexes on clustering goodness (like the well known Connectivity, Dunn, and Silhouette) with no positive result, and we leave for future work the study of other feasible a priori approaches to find m .

Once the m clusters are formed, the probably most natural algorithm for selecting the topics from the clusters is as follows. Considering the one-for-cluster series, there exist three possibilities for each cardinality $c \in \{1, \dots, n\}$:

- Case $c < m$: we select randomly c clusters, and then we select c elements, one for each cluster.
- Case $c = m$: we select one topic per cluster, as we did in the case of cardinality-driven clustering (Section 6.2).
- Case $c > m$: we select m topics as in the previous $c = m$ case; we then repeat for the remaining $c - m$, until we fall in the first $c < m$ case. When a cluster becomes empty during the process, we skip it in the following iterations.

Note that cardinality-driven and cardinality-independent clustering coincide only when $c = m$.

6.3.2 Cardinality-independent Clustering on the Simulated Example

Figure 9 shows the results for cardinality-independent clustering for the same simulated experiment. The figure shows that in general, we obtain topic subsets that always have higher τ values than the average; this holds for almost all the s , r , and ϵ values.

Also, there are several positive peaks in the series. These occur at cardinalities corresponding to multiples of the number of topic seeds s ; e.g. considering $s = 15$, the positive peaks are around cardinalities 15, 30, 45, and so on. This is an indication that multiple effective m values exist. Indeed, clustering is effective not only for m corresponding exactly to the cardinalities of the peaks, but also for near values, and this fact can be exploited for m selection.

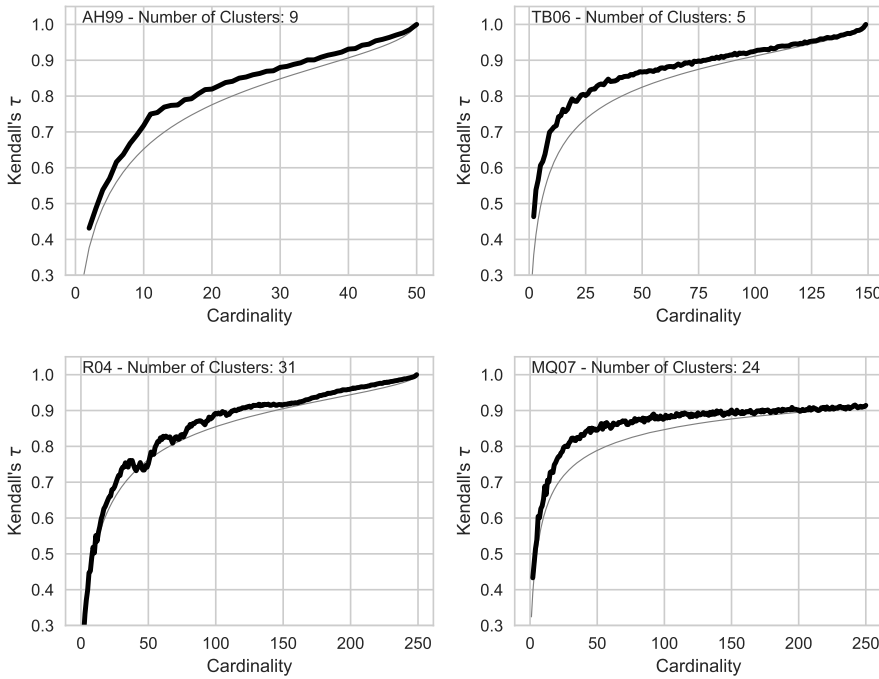

Fig. 10 Kendall's τ correlation curves for the four datasets: averaged (thinner gray lines), and obtained using clustering (thicker darker lines).

Finally, the lower negative peaks of Figure 8 almost disappear, even for the largest ϵ value of 0.05: even if the topics are difficult to cluster, the clustering process is still effective.

6.3.3 Cardinality-independent Clustering on Real Data

Figure 10 shows the results of cardinality-independent clustering for the real-data experiment, for some selected m values, corresponding to the cardinalities of the positive peaks of the series of Figure 7: 9 clusters for AH99, 5 clusters for TB06, 31 clusters for R04, and 24 clusters for MQ07. We choose to report the results corresponding to the highest peak at the lowest possible cardinality: for AH99 a similar behavior is found for cardinalities 16, and 31, for TB06 for cardinalities 22, 43, 45, and 75, for R04 for cardinalities 16, 25, 31, 45, 60, and 75, and finally for MQ07 for cardinality 64.

The figure shows that the one-for-cluster series always has higher τ values than the average series, for all the collections, with a single exception for R04. Cardinality-independent clustering is effective. It is also interesting to remark that, as we have seen in Section 6.2, in the cardinality-driven clustering, even with PCA, the one-for-cluster series is often significantly lower than the average in the artificial experiment (see Figure 8) and sometimes lower in

the real datasets (see Figure 7). On the contrary, in cardinality-independent clustering this never happens: in the least favorable case, the one-for-cluster and average series are equivalent (the series overlap).

We also verified that the series oscillations do not depend on noise, as they still occur with 1M repetitions, as noted previously (see Footnote 7): the one-for-cluster series always fluctuates a little, but these oscillations are small and do not affect the results.

Another final result is that, in cardinality-independent clustering, the choice of the number of clusters m can be critical. A detailed analysis of our data shows that good m values can be found by looking at the positive peaks on the one-for-cluster series of the cardinality-driven clustering. For the m values corresponding to the cardinalities of such peaks, as well as the nearest cardinalities, the one-for-cluster series of the cardinality-independent clustering tend to have higher τ values than the average series, for almost any cardinality. It has to be noted that these are not all the good m values, as there exist other m values such that for the cardinality-independent clustering the one-for-cluster series is always above the average, but there is not a corresponding peak in the cardinality-driven clustering. However, this provides a general criterion for the choice of m . For example, considering our datasets, to obtain one-for-cluster series that are better than random topic selection: for AH99 any m value can be used (but cardinalities around 8, 15, and 30 are better), for TB06 the best values are around 10, for R04 the best values are 25, 75, and 110; and, finally, for MQ07 the best values are around 25, 45, and 60.

6.4 Discussion

The above results show that cardinality-independent clustering of topics is an a posteriori topic selection strategy that is more effective than the random selection of topics. The effectiveness increase is still not large but it is consistent across all cardinalities and collections. As all the other results of this line of research, this is an a posteriori strategy that is only potentially useful and cannot be applied in practice. However, it can give useful insights for a priori strategies, like suggesting the number of clusters to be used.

Note that although the setting is still a posteriori, clustering of topics shows only a limited effectiveness as a strategy to find good topic subsets. That is, even if we focused on a context where we expected clustering to be clearly effective, this was not the case. This is perhaps surprising and might even cast some doubts on the effectiveness of clustering also for an a priori approach; however, in that case the features used would be very different, and therefore this claim needs to be verified with further experiment, that we leave as future work.

As a final remark, we conjecture that one general reason for the less than satisfactory effectiveness obtained with a posteriori clustering could simply be a “tyranny of majority” effect. If there is a large subset of topics that can be “naturally clustered” together, and that cluster is indeed recognized by

the clustering algorithm (as is quite likely), then the one-for-cluster selection method will be forced to pick up just one topic from that largest cluster. However, the topics in that large natural cluster are driving the evaluation in a specific direction – these topics “weigh more” than the other topics. This will result in penalizing the one-for-cluster selection method, that is forced to not recognize this majority. This conjecture is true at least to some extent in our datasets: in our experiments the largest cluster usually contained around 75–90% of the topics. We leave further analysis of this issue as future work.

7 Conclusions and Future Work

Compared to previous work on using fewer topics in the evaluation of IR systems, our contributions are threefold. Addressing RQ1, we show that examining subsets of a larger ground truth topic set results in average and best subsets that are much more correlated with the ground truth topic set than found in previous work (Guiver et al, 2009; Robertson, 2011; Berto et al, 2013). It would appear that as the cardinality of the ground truth increases, the size of the subset (relative to ground truth) required to obtain a high correlation also decreases.

We also find that under large cardinalities, worst topic subsets are notably worse than shown in past work. Although finding a few bad topics was perhaps to be expected, when a larger pool of topics could be drawn from the large size of worst topic subsets that still had very low correlations was striking. Examination of the effectiveness of worst subsets shows that they were mainly composed of topics with poor effectiveness scores.

Addressing RQ2, we analyze the role of statistically significant differences between runs for different topics subsets. The ability to distinguish statistically between the effectiveness of two runs is impaired when topic cardinality is lowered. The main problem is an increase in false negatives (type II errors) when making comparisons. This issue has not been shown before in this area of topic subsetting research. Some subsets were shown to be better than others at minimizing type I and II errors. The analysis showed that the level of error reduced relatively quickly as subset cardinality increased. Nevertheless, because all of our experiments still use relatively small populations of topics when compared to “the set of all topics in the world”, it is not clear if the level of type II error will reduce sufficiently. The collections still don’t give us a sense of what the “true” population of possible topics is like, and we have no way to be sure that the full cardinality is the truth. In a way, the results in this paper suggest that all test collections are suspect, since their very small subset of topics might be completely un-correlated with the “true” population of all possible topics.

Our findings on the overlap of best and worst topics sets confirm that being a good topic largely depends on the other topics in the subset. In general, the previously established terminology of best/worst topic sets is perhaps misleading since it can be argued that the worst topics are actually the most

interesting ones (they rank runs in ways contrary to the majority of topics), whereas the best topics feature a high degree of redundancy that might lead to a waste of resources. Indeed, the high degree of redundancy is manifested in the best correlation curves, that have high correlation values also for low cardinalities.

Addressing RQ3, our analysis showed that clustering is effective in finding topic subsets that are more representative than simply taking average or random subsets, as long as the clustering is combined with dimensionality reduction. However, the topic subsets obtained by clustering do not feature correlations that are as high as the best topic sets. While the work here is a first step in finding representative and effective topic subsets, there is still much work to be done to improve topic subset selection.

In future work, we plan to consider the correlation between topic subsets (rather than between a topic subset and the full topic set) as well as top-heavy measures of association such as Rank Biased Overlap or τ_{AP} , to give more importance to the most effective systems. We have only started to analyze how best and worst topic sets are formed. Considering the extreme nature of Best and Worst series, extreme value theory might be useful to better understand and model the stochastic behavior of Best / Worst series and topic subset distributions. We also plan to deepen the analysis by finding more semantic features that characterize a good/bad topic set. Indeed, as in previous research, we have not attempted to devise methods to find good topic subsets before the evaluation exercise is performed, or while it is ongoing; the focus of our research so far has been on working to understand how different topic sets interact. Future work studying more semantic topic features, combined with many runs, will hopefully help to provide a set of guidelines for sound topic set engineering.
